Maps of projected changes - Maps show the projection of change over this century (mean of the period 2071-2100 compared to the mean of the period 1961-1990) under the “High” emission scenario. In the left panel, changes in greenwater consumption are shown and in the right panel, changes in evapotranspiration.

List of projected changes - The tables show the mean of the projected changes in respectively the evapotranspiration, greenwater consumption and water stress (rounded values). Note that current land use is used in this study for all assessed time periods. Consequently all changes are caused by climate change alone.

Note: Increasing values in the green water consumption indicate that more water becomes available for agricultural production. This may be caused by either increasing rainfall amounts, increasing CO2 levels or a combination of both. The decreasing values in evapotranspiration indicate that the increasing CO2 concentration has a stronger effect than the increasing temperatures.

Key findings for Zone 3

- Based on the analyzed ensemble of global climate projections under the assumption of a low and a high emission scenario it can be concluded that rainfall increases. The evapotranspiration is not changing much. Agricultural production is not hampered by water shortages. Crop damage may occur due to flooding, excess of water and diseases related to high air humidity. As the precipitation amounts increase this may occur more frequent. The simulated biomass increases, indicating that the agricultural production increases.

Key adaptation options

- Improved flood management plans to ensure limited damages to agricultural systems during high rainfall events.
- Reducing erosion risk and nutrient leaching by introduction of agroforestry systems
- To adapt to increased climate variability farming systems should become more diverse. This can be done for example by planting multiple crops and using different varieties.
Climate Change Scenarios for the Congo Basin

**Maps of projected changes** - Maps show the projection of change over this century (mean of the period 2071-2100 compared to the mean of the period 1961-1990) under the “High” emission scenario. In the left panel, changes in greenwater consumption are shown and in the right panel, changes in evapotranspiration.

**Definition of Zone 4** - The map below indicates the position of Zone 4 (red rectangle), representing the regions north of the equator with predominantly tropical wet and dry climates with a dedicated rainy season. All values presented in this fact-sheet are changes spatially averaged over the whole zone. As the western part of DRC falls within Zone 4, projected changes for this zone are assumed to be representative for this part of the country.

**List of projected changes** - The tables show the mean of the projected changes in respectively the evapotranspiration, greenwater consumption and water stress (rounded values). Note that current land use is used in this study for all assessed time periods. Consequently all changes are caused by climate change alone.

**Data and method** - The projected greenwater, evapotranspiration and water stress signals are based on the LPJ-ml Dynamic Global Vegetation model (DGVM) forced by the bias-corrected ECHAM global climate change projections. Projected changes in the climate are assessed for two different greenhouse gas emission scenarios: the “Low” scenario is based upon the SRES B1 (IPCC-AR4) scenario; the “High” scenario is based upon the SRES A2 (IPCC-AR4) scenario. We present the area-averaged mean change, based upon only one climate model, the ECHAM scenario, as this was the only one giving acceptable results. Land use changes up to 2006 have been used. Projections for the future land use depend on many unknown factors and are therefore difficult to incorporate. The data presented here reflect the changes that are only caused by the changing climate i.e. land use is kept constant. Increasing temperature and the rising atmospheric CO2 concentration have an opposite effect on agricultural production. The increasing temperature results in an increasing soil evapotranspiration whereas the rising CO2 concentration reduces plant transpiration especially in the C4-crops. Unfortunately little is known on the interaction of the rising CO2 concentration, fertilizer inputs and increasing temperatures for tropical crops. More research in this direction is needed. Note that changing agricultural practices such as more inputs, new crop varieties etc. may have a strong positive effect on the future agricultural production and may compensate for the negative climate change impacts.

**Key findings for Zone 4**
- Based on the analyzed ensemble of global climate projections under the assumption of a low and a high emission scenario it can be concluded that rainfall increases (10-20%). The evapotranspiration is not changing much whereas the greenwater consumption initially is increasing, indicating that more water comes available for the agricultural production at the beginning of the century. Halfway the century it stagnates and the water availability does not change much. The biomass (vegetation carbon) is decreasing in this period which indicates that the agricultural production may decrease if the current farming systems and techniques are applied in this period. In the northern regions, agriculture may experience occasional crop damage due to an excess of rainfall. In the south occasional droughts will occur.

**Key adaptation options**
- Improved flood management plans to ensure limited damages to agricultural systems during high rainfall events.
- Reducing erosion risk and nutrient leaching by introduction of agroforestry systems.
- To adapt to increased climate variability farming systems should become more diverse. This can be done for example by planting multiple crops and using different varieties.
- Improved management of climate variability to ensure maximum yield during high rainfall years and minimum damage during dry years.
Maps of projected changes - Maps show the projection of change over this century (mean of the period 2071-2100 compared to the mean of the period 1961-1990) under the “High” emission scenario. Note that current land use is used in this study for all assessed time periods. Consequently all changes are caused by climate change alone.

Key findings for Zone 5
• Based on the analyzed ensemble of global climate projections under the assumption of a low and a high emission scenario it can be concluded that rainfall slightly increases (0-10%). The evapotranspiration decreases slightly. On the other hand the green water consumption initially increases (15-18%), however halfway the century this increase stop. This indicates that initially more water comes available for the agricultural production, however halfway the century available water remains stable. The biomass (vegetation carbon) is decreasing in this period which indicates that the agricultural production may decrease if the current farming systems and techniques are applied in this period. Note that the southern regions may experience droughts.

Data and method - The projected green water, evapotranspiration and water stress signals are based on the LPJ-mL Dynamic Global Vegetation model (DGVM) forced by the bias-corrected ECHAM global climate change projections. Projected changes in the climate are assessed for two different greenhouse gas emission scenarios: the “Low” scenario is based upon only one climate model, the ECHAM scenario, as this was the only one giving acceptable results.
